## [57] <br> ABSTRACT

A method and apparatus for the identification of spatial patterns that occur in two or more scenes or maps. Each pattern comprises a set of points in a spatial coordinate system collectively represented by the geometrical figure formed by connecting all point pairs by straight lines. The pattern recognition process is one of recognizing congruent geometrical figures. Two geometrical figures are congruent if all the lines in one geometrical figure are of the same length as the corresponding lines in the other. This concept is valid in a spatial coordinate system of any number of dimensions. In two- or threedimensional space, a geometrical figure may be considered as a polygon or polyhedron, respectively. Using the coordinates of the points in a pair of congruent geometrical figures, one in a scene and the other in a map, a least squares error transformation matrix may be found to map points in the scene into the map. Using the transformation matrix, the map may be updated and extended with points from the scene. If the scene is produced by the sensor system of a vehicle moving through an environment containing features at rest, the position and orientation of the vehicle may be charted, and, over a series of scenes, the course of the vehicle may be tracked. If the scenes are produced by a sensor system at rest, then moving objects and patterns in the field of view may be tracked.

## METHOD AND APPARATUS FOR TRACKING, MAPPING AND RECOGNITION OF SPATIAL PATTERNS

## I. BACKGROUND-FIELD OF INVENTION

The invention concerns methods and apparatus for the recognition, tracking and mapping of spatial patterns for a variety of uses.

## II. BACKGROUND-DESCRIPTION OF PRIOR ART

The background may be divided into three connected parts: method, apparatus and applications:

## A. Method

The fundamental process is one of recognition of unique spatial patterns that recur in two or more scenes. A comprehensive reference of the existing methods is given by Paul J. Besl in his article, "Geometric Modeling and Computer Vision," Proceedings of the IEEE, pages 936 to 958, Volume 76, Number 8, August 1988. The methods may be divided into two main categories: linear and nonlinear. The method of the invention falls in the latter category.
A. 1 Linear methods:

The linear methods are based on the crosscorrelation process, which is inherently linear. It has a number of drawbacks, however. One drawback is that it requires a large amount of computation power. Attempts to improve the computational efficiency include hierarchical correlation processing and hierarchical organization of the scene. Another drawback is its inefficiency in dealing with patterns of unknown rotation. To remedy this problem, there have been several attempts, in both space and wave number domains, to develop rotation invariant methods. In all cases, the computational efficiency could only be increased at the expense of reduced scene resolution and a degradation in the recognition performance. In applications where there is a large amount of redundancy in the pattern, such as in the recognition of printed text, this is not a serious drawback. A third drawback is the tendency of the crosscorrelation process to give ambiguous or false results when the scene is noisy, imperfect or incomplete.
A. 2 Nonlinear methods

The nonlinear methods are a loose collection of heuristic methods based on feature extraction and pattern matching concepts, in which the position and orientation of a set of features in a spatial coordinate system is termed a pattern. In a two-dimensional scene, features may include discrete points, texture, gray scale, lines, curves and corners, and planar surfaces. In a two-dimensional space, the pattern formed by a set of points may be represented by a polygon, and in a three-dimensional space, a polyhedron. Feature extraction and pattern matching have been successfully applied to certain types of optical and radar images, and in the recognition of printed and handwritten text.
The method of the invention is one of recognizing patterns that may be considered as geometrical figures, including polygons and polyhedrons. In practice, the computation resources and computation time required by the existing methods of recognizing polygons and polyhedrons increase sharply with scene complexity, therefore they are most useful when applied to simple scenes or selected parts of complicated scenes. This is
quite acceptable for scenes which contain simple patterns or complicated patterns with much redundancy, but not for cluttered scenes that may contain incomplete patterns with little redundancy. In this respect, the method of the invention is superior to existing methods.

## B. Apparatus

The invention is expected to be particularly useful in practical applications of pattern recognition, where the available space and electrical power are limited. These limitations impose definite constraints on the design of the apparatus. For example, in an autonomous underwater vehicle, it is estimated that a few tens of watts of electrical power may be available for navigation and guidance computations. Using CMOS technology, it is possible to achieve processing rates of more than 10 million integer multiply-and-accumulate operations per second (Mmacs) for a power consumption of only one watt. Therefore, an acceptable navigation processor should not require more than a few hundred Mmacs of processing power. These constraints effectively exclude a large proportion of the above mentioned methods from applications in autonomous underwater vehicles.

## C. Applications

The invention is expected to be particularly useful to applications in autonomous navigation. There are a number of autonomous navigation system in existence. They include ballistic missile and cruise missle guidance systems. Equivalent systems for autonomous underwater or land vehicles, that can guide an unmanned craft to its destination over long distances, are still in their infancy. The navigation methods and equipment of existing unmanned autonomous underwater vehicles, described by Stephen H Eppig in a paper entitled, "Autonomous vehicles for underwater search and survey," presented at the 4th International Symposium on Unmanned Untethered Submersible Technology June 24-27 1985, are based on a combination of inertial navigation system aided by Doppler or correlation sonars with periodic course corrections provided by acoustic ranging. Acoustic ranging systems rely on a network of acoustic transponders that must be deployed at strategic positions within the operating area, therefore they cannot be considered as selfcontained systems. The Doppler or correlation sonars provide a measurement of cruising velocity that may be integrated to give an estimate of the distance traveled. In conjunction with an inertial navigation system, the velocity measurements may be used to estimate course and position relative to a set of known starting coordinates.
Systems based on the Doppler or correlation sonars are the only selfcontained underwater navigation systems currently available, i.e. systems that do not require external equipment such as beacons or transponders. Both types of sonars are inclined to give velocity measurement errors, particularly over sloping ocean bottoms or moving scattering layers. The resulting error in the position estimation is cumulative, therefore, corrective position fixes by other means are necessary at periodic intervals. Systems based on velocity measurement and integration are also incapable of recognizing previously traversed areas. Apart from this invention, there are no selfcontained systems that can successfully navigate by the tracking and recognition of naturally occurring features on the ocean bottom; contributing factors include the relative scarcity of information in sonar
images and the substantial computation resources required by existing methods. The method of the invention is successful because it is particularly efficient in its use of information and computation resources.

## III. OBJECTS AND ADVANTAGES

Accordingly I claim the following as objects and advantages of this invention: to provide a method and apparatus for the recognition, tracking and mapping of spatial patterns, using a pattern recognition process whose distinguishing features are (a) the concept of congruent geometrical figures and (b) a maximum likelihood method of efficiency enhancement.

In addition, I claim the following objects and advantages: to provide a method and apparatus that facilitates the navigation of manned or unmanned vehicles through the recognition, tracking and mapping of spatial patterns formed by environmental features, to provide a method and apparatus to produce and store feature maps, to provide a method and apparatus to recognize previously encountered areas and to track vehicle position and orientation with the aid of feature maps.
Further objects and advantages of the invention may be found from the ensuing description and accompanying drawings.

## VI. DESCRIPTION

In the following, the invention in and its application in the navigation of a vehicle is described. The navigation application is described because it well illustrates the operation of the invention. The description is given in two levels: concept and process. At the concept level, a qualitative description is given of the invention and its uses as a navigation tool. At the process level, the operation of the invention within a navigation system is described in detail.

## A. Concept

Consider a vehicle, traveling through an environment in which there are a number of features, and equipped with a sensor system that is able to detect the features and to estimate the position of each feature relative to the vehicle. Practical examples include: a space craft equipped with an optical imaging and ranging system traveling through a planetary system, an aircraft equipped with radar traveling over a terrestrial area, and an underwater vehicle equipped with sonar traveling over the ocean bottom. In the first example, the relevant features may be celestial objects, in the second example, telephone poles, trees and other landmarks that are detectable by a radar system, and in the third 40 example, rocks, clumps of coral and other features of the ocean bottom that are detectable by a sonar system.

In FIG. 1, a vehicle is shown traveling over an area containing discrete features $\mathbf{1}$ that are detectable to its sensor system. The illustration shows the vehicle at a 5 previous position 2 and its current position 3. At the previous position 2, the vehicle has a certain field of view 4 , in which it detects a number of the features. Let the field of view 5 at the current position overlap the field of view 4 at the previous position. For each field of view, the sensor system provides a set of information, called a scene, comprising the signal intensities produced by the detected features and their estimated positions relative to the vehicle. The position of each feature is represented by a single point in a spatial coordi5 nate system. A number of features 6 lie within the intersection of the two fields of view, consequently they must be represented in the two corresponding scenes. An apparatus, that can recognize and match the points representing the common features 6 in the two scenes,
60 will enable the vehicle to track its movement from the previous position 2 to the current position 3.

Using the positional information provided by the sensor system, straight lines may be used to connect any set of points within a scene to form a geometrical figure.
65 The geometrical figure is uniquely defined by the lights of the lines joining all point pairs within the set. This concept is valid in a spatial coordinate system of any number of dimensions. In a two- or three-dimensional
space, the geometrical figure may be considered as a polygon or polyhedron, respectively. By this concept, the common features 6 may be described as a geometrical figure. If all the lines in one geometrical figure are of the same length as the corresponding lines in another geometrical figure, then the two are said to be congruent. It follows from the above definition of the geometrical figure that identical geometrical figures must be congruent. Therefore, the process of recognizing common features in two fields of view may be formulated as one of recognizing congruent geometrical figures between the two corresponding scenes.
The geometrical figure formed by the common features 6 , and the positions of the vehicle relative to it, are illustrated in FIG. 2. The vehicle positions 2 and 3, relative to the geometrical figure, are constructed from the positional information contained in the two scenes. The change in position of the vehicle from 2 to 3 is equal to the difference between the two position vectors.
In general, a map may be defined as a collection of points in space whose positions relative to accepted geographical references are known, or considered to be known. If the previous position and orientation of the vehicle 2 is known or considered to be known, then the corresponding scene may be converted into a map. Through the recognition congruent geometrical figures, the current vehicle position may be charted on the map.
With reference to FIG. 3, if a map 7 of an operating area were available, then congruent geometrical figures between a current scene 8 and the map may be used to chart the position of the vehicle 9 in the map. In this way, the course and position of the vehicle may be continuously tracked. This concept may be used to guide a vehicle from a starting position 10 to its destination 11, as illustrated in FIG. 3.
In the absence of a map, a vehicle may guide itself towards a designated destination 11, defined in terms of a distance and bearing from a known starting orientation and position 10, through the following steps: Using the known starting position and orientation, the contents of a scene acquired at the starting position and orientation may be converted into a map. Then, through a series of overlapping scenes linked by congruent geometrical figures, the map may be extended in the direction of the destination by the accumulation of interlocking geometrical figures, as illustrated in FIG. 4. The process may be continued until the requisite distance is covered.

## B. Process

A description of the invention and its application to vehicle navigation will be given, with particular emphasis on underwater vehicles. A simplified flowchart of a navigation system is shown in FIG. 5. The navigation processor 12 is driven by the mission objectives 13. A sensor system 14 is used to provide the navigation processor with scenes that represent features in the environment. The navigation processor may be subdivided into two component processors, a position and orientation tracking processor 15, and a steering an speed correction processor 16 ; both may request the sensor system to provide a new current scene 8 as necessary. The steering an speed correction processor drives a steering and speed controller 17 which operates the steering and propulsion units, thus closing the control loop.

## component processors described as follows.

B.2.a Clustering processor: In practice, the position of every point in a scene is subject to a degree of uncertainty. At any given level of confidence, the uncertainty may be expressed in terms of a confidence interval.
50 Using simple decision theory methods, the confidence interval of the position of a point is calculated from the feature location accuracy of the sensor system and the selected confidence level. The feature location accuracy of the sensor system is determined by physical factors and the characteristics of the sensor system. The selected confidence level is a parameter with possible values between 0 and $100 \%$; while there are no set rules regarding its proper value, intermediate values have been found to give satisfactory results.
In practice, more than one data point may be found within the span of a confidence interval. The presence of more than one data point within a confidence interval represents an unnecessary redundancy. Therefore, a clustering processor $\mathbf{1 8}$ is used to identify groups of two or more points that occupy a space too small to be reliably resolved by the sensor system at the selected confidence level, and replace each group by a single representative data point at the centroid of the group;
the centroid is defined as the average position weighted by signal intensity. Then, a unique identifier is assigned to each data point. An identifier may be a character string, bit pattern or any other suitable form of symbolic information. The result is a compacted scene 19.
B.2.b The spatial pattern recognition processor: The operation of the spatial pattern recognition processor 20 is based on the criterion:
Two geometrical figures are congruent if the straight lines connecting all corresponding point pairs are of 10 equal length.
A straight line is defined as the shortest path between two points in a space of one or more dimensions, not necessarily limited to three dimensions.

Before going into the description of the processor itself, there are two important practical aspects that need to be considered, line length accuracy and recognition performance.

Just as there are uncertainties associated with the point positions, there must be uncertainties associated with the length of lines joining pairs of points. This uncertainty may also be allowed for in the form of a confidence interval. Thus, two line lengths are considered equal if the difference is within their combined confidence interval. The combined confidence interval may be approximated by the incoherent sum of the resolved confidence intervals of the positions of the four end points.
As a consequence of line length uncertainties and other imperfections, it must be concluded that, in practice, there is a finite probability that the performance of the recognition processor may be less than perfect. Following standard decision theory methodology, the performance may be expressed in terms of the probability of detection and the probability of false alarm; in this context, "detection" refers to the proper recognition of congruent geometrical figures, and "false alarm" refers to a false recognition. In order to achieve or exceed a prescribed level of performance, it can be shown that the number of points in the congruent geometrical figures must be equal to or exceed a minimum threshold number. The said threshold number may be calculated from the required probabilities of detection and false alarm, the confidence intervals of the point positions, the dimensions of the compacted scene and the relevant region of the map, and the average densities of the points in the compacted scene and in the map.

Using information available to the navigation system, such as estimated vehicle velocity and elapsed time, it is often possible to limit the search to a relevant region in the map containing all the points that may be expected to form a geometrical figure congruent with another in the compacted scene. Similar search limits may also be applicable within the compacted scene. These limits can help improve performance and reduce costs. By calculating all the combinations and permutations that have to be tested, and given the above practical considerations, it can be shown that, to achieve a useful level of performance, a direct search, of scenes and maps produced by sonars, would be prohibitively costly in terms of search time and computation resources. A significantly more efficient method, embodied in the spatial pattern recognition processor 20, is hereby disclosed.

The spatial pattern recognition processor 20 may be divided into three parts:
(1) A processor 21 is used for comparing the lengths of straight lines between point pairs in the compacted scene to those of a relevant set of point pairs in the map
(a) selecting and permanently removing an initial pair of matched lines from the list 24 and advancing to the next higher step (b),
(b) searching the list, using an efficient method such as a binary search, to find two pairs of matched lines to connect the initial pair of lines with a third pair of points and form a pair of congruent triangles, and if found: temporarily removing the two pairs of matched lines from the list and advancing to the next higher step (c), but if not found: restoring to the list all matched lines temporarily removed, and returning to (a) for a new initial pair of matched lines,
(c) searching the list, using an efficient method such as a binary search, to find three pairs of matched liens to connect a new pair of points with all points in the congruent triangles and form a pair of congruent tetrahedrons, and if found: temporarily removing the three pairs of matched lines from the list and advancing up to the next higher step (d), but if not found: removing from the congruent triangles the two matched lines added in the adjacent lower step (b), restoring to the list any matched lines temporarily removed at this and higher steps, and returning to the adjacent lower step (b),
(d) and all higher steps:
searching the list, using an efficient method such as a binary search, to find additional matched lines to connect a new pair of points with all points in the pair of congruent geometrical figures and form a pair of congruent geometrical figures containing an additional pair of points, and if found: temporarily removing the additional matched lines from the list and advancing to the next higher adjacent step, but if not found: removing from the congruent geometrical figures the matched lines added in the adjacent lower step, restoring to the list any matched lines temporarily removed at this and higher steps, and returning to the adjacent lower step to continue the search.
The spatial pattern recognition processor 20 is a key part of the invention. The list reduction processor 23 is the crucial component that gives the spatial pattern recognition processor its conspicuous efficiency. The sequential arrangement of the component processors and the separation of the arithmetic and symbolic operations, whereby the processors in parts (1) and (2) perform mainly numerical arithmetic operations, while those in part (3) perform only symbolic operations, have practical advantages. The former allows the use of multiple processors arranged in a production line for fast real time processing. The latter allows the use of separately optimized symbolic and arithmetic processors, which should be more efficient than using general purpose processors to perform both types of operations.
B.2.c Map update: Using the coordinates of the points 5 contained in the congruent geometrical FIGS. 26, a processor 27 is used to for computing a least-squareserror coordinate transformation matrix to properly map the points in the compacted scene 19 into the map 7. Optionally, independent heading information from another instrument such as a magnetic compass may be used to confirm or improve the rotation component of the transformation. The use of independent heading information may reduce charting errors when the map is being extended into uncharted regions.

A processor 28 is used for updating the map with the contents of the current scene through the transformation matrix produced by 27 , including the follow steps:
(a) mapping the points from the compacted scene into the map using the transformation matrix,
(b) entering points mapped from the compacted scene into the map on a contingency basis where their confidence intervals do not overlap the confidence intervals of existing points in the map,
(c) confirming existing points in the map where their confidence intervals overlap the confidence intervals of the mapped points,
(d) removing points from the map that were entered on a contingency basis from previous scenes and lie within the field of view, but whose confidence intervals consistently fail to overlap those of points mapped from this and other compacted scenes
B.2.d The vehicle velocity, position and orientation computation processor: A processor 29 is used for computing the position and orientation of the vehicle in the map by applying the transformation matrix produced by 27 to the vehicle orientation and position at the origin of the coordinate system of the compacted scene, compiling a time history of the position and orientation of the vehicle, and estimating the velocities of the vehicle from the time history.
B.3. Steering and speed correction processor Returning to FIG. $\mathbf{5}$, the steering and speed correction processor 16 is used for comparing the time history of the position and orientation of the vehicle produced by 15 with the desired course and speed dictated by the mission objectives 13, computing the corrective measures necessary to achieve and maintain the appropriate course and speed consistent with the mission objectives, and checking that the corrections are effective, by requesting a new current scene from the sensor system for processing at appropriate times. The corrective measures are put into effect by the steering and speed controller 17, thus closing the control loop.

## C. Testing

The operation of the invention was tested by computer simulation. With reference to FIG. 5, an existing sonar system of the Applied Research Laboratories of the University of Texas at Austin was used as the sensor system 14 to generate the map 7 and the current scene 8 in a digital form. The essential components of the invention, which is contained in the position and orientation tracking processor 15, specifically the clustering processor 18 through the coordinate transformation matrix computation processor 27 in FIG. 6, were simulated in three stages:
(1) The first stage, which included the clustering processor 18, compacted scene 19, the list of matched lines compilation processor 21, list of matched lines 22, and the list of matched lines reduction processor 23, produced the the reduced list of matched lines 24 . The first stage was simulated in a computer program called PREAT5, written in FORTRAN by Ann Clancy, and executed on a CDC CYBER 830 computer manufactured by the Control Data Corporation.
(2) The second stage, which included the congruent geometrical figures recognition processor 25 , extracted the congruent geometrical FIGS. 26 from the reduced list of matched lines 24 . The second stage was initially simulated in a computer program called LISPCODE-DEV-6, written LISP by Douglas K. Walker and executed on a Macintosh computer under the ExperLisp system. The Macintosh computer is manufactured by Apple Computer Inc. and the ExperLisp software system is produced by ExperTelligence Inc. However,

LISPCODE-DEV-6 was found to occasionally give erroneous results. The problem was solved by replacing LIPSCODE-DEV-6 with a program called CFGIF, written by the applicant in Microsoft Excel macro language on a Macintosh computer. Microsoft Excel is a spreadsheet software system produced by the Microsoft Corporation.
(3) The third stage, which included the coordinate transformation matrix computation processor 27, computed a coordinate transformation matrix from the congruent geometrical FIGS. 26 provided by the second stage. The third stage was simulated in a program called

SENSOR TRACKING, written by the applicant as a Microsoft Excel spreadsheet on a Macintosh computer.

Using real data from a moving sonar that was periodically sensing the seafloor, said coordinate transformation matrix obtained by said computer simulation was checked against independent references computed by acoustic and radio navigation methods. The test was repeated with several data sets. The test results indicated that the method of the invention is sound. Listings of the programs PREAT5, LISPCODE-DEV-6, CFGIF and SENSOR TRACKING are given in the Appendix.

position and orientation between said congruent geometrical figures.
2. A navigational system comprising:
means for periodically generating a scene comprising
a plurality of data points, each said data point possi-
bly representing a feature in the environment, said generating means including:
sensing means for periodically sensing the presence and position of said features;
means for consolidating groups of said sensed features that are too closely clustered to be reliably resolved by said sensing means including:
means for identifying clusters of two or more sensed features that occupy a spaced too small to be reliably resolved by said sensing means; and
means for replacing each said cluster by a single sensed feature located at the center of said cluster; and
means for storing a data point to represent each said sensed feature, said data point comprising its position and a unique identifier;
means for prestoring a map comprising a plurality of
data points representing reference features;
means for determining a coordinate transformation
matrix between said scene and said map, said deter-
mining means including:
means for recognizing a geometrical figure in said scene that is exclusively congruent with another geometrical figure in said map, said recognizing means including:
means for generating a list of matched lines, including:
means for calculating the length of the straight line between any two said data points;
means for determining if a said straight line in said scene matches another said straight line in said map in length within the limits of accuracy of said sensing means;
means for systematically searching for said matched lines; and
means for storing said matched lines according to said identifiers of their terminations;
means for reducing said list of matched lines, said reducing means including:
means for accumulating a tally of the number of said pairs of matched lines that a said data point in said scene shares with a said data point in said map, for all combinations thereof;
means for generating a list of likely matched points, including means for pairing each said data point in said scene with the data point in said map with which it shares the largest said tally; means for pairing each said data point in said map with the data point in said scene with which it shares the largest said tally; and means for storing said point pairs in said list of likely matched points in a systematic manner according to their said identifiers; and
means for eliminating from said list of matched lines those matched lines that do not connect any two pairs of said likely matched points; and
means for searching said list of matched lines for a geometrical figure in said scene that is exclu-

## 79

sively congruent with a geometrical figure in said map; and
means for computing said coordinate transformation matrix from the relative displacements in position and orientation between said congruent geometrical figures; and
means for updating the position and heading of said navigational system from said coordinate transformation matrix.
3. A navigational system of claim 2 wherein said 10 sensing means comprises a sonar set.
4. A navigational system of claim 2 wherein said
